Abstract – Recent collections of specimens from the Pilbara attributed to *Leggadina lakedownensis* stimulated an investigation of genetic and morphometric variation in *L. lakedownensis* and *L. forresti* to confirm the taxonomic status of these species, determine the extent of intraspecific variation, and develop useful markers for classification. Extensive analyses of both morphology and allozymes confirm the clear taxonomic separation of these two species. *Leggadina lakedownensis* shows considerably more intraspecific morphological variation than *L. forresti*, reflecting the former's much greater geographic range and ecological diversity. The mean body size of Thevenard Island *L. lakedownensis* is markedly larger than the other populations examined. Despite this morphological diversity, populations of *L. lakedownensis*, including those from mainland Pilbara and Thevenard Island, are genetically similar across their range. An individual from Queensland is genetically the most divergent but we have been unable to assess the morphological relationship of the topotypical population.

INTRODUCTION

The genus *Leggadina* has a wide distribution across mainland Australia, with two allopatric species currently recognised, *L. forresti* (Thomas, 1906) from central Australia and *L. lakedownensis* (Watts, 1976), broadly distributed across northern Australia (Figure 1). Baverstock *et al.* (1976) presented biochemical and karyotypic evidence to firmly establish the specific distinction of *L. lakedownensis*, then known only from a restricted area of northeast Queensland, from the more widely distributed *Leggadina forresti*.

Since these initial studies, many different populations of *Leggadina* have been sampled, especially in the Kimberley and Pilbara regions of Western Australia. Although some of these populations have been referred to *L. lakedownensis*, this attribution has not been critically examined. In addition, animals from Thevenard Island, off the Pilbara coast, are much larger than mainland populations of *Leggadina*, and this has led to some concern over the taxonomic status and conservation needs of this morphologically-distinctive form. Moro *et al.* (1998) examined variation in mitochondrial DNA (mtDNA) from Western Australia and Northern Territory populations referred to *Leggadina lakedownensis* and found significant lineage divergence between the Pilbara (including Thevenard Island) and Kimberley populations of this species. On this basis they suggested that the Pilbara and Thevenard Island specimens together might represent a distinct subspecies. Moro *et al.* (1998) did not include any specimens from northeast Queensland in their analyses.

Prior to 1997, only two specimens of *Leggadina* had been collected in the Pilbara region. Since that time, thirty specimens, some with tissue for molecular analysis, have been collected during various surveys of the region. The availability of this new material has prompted us to conduct a comprehensive morphological and genetic study of *Leggadina* across its geographic range. The purposes of this study were to re-assess species boundaries in the genus using morphological and allozyme data, and to examine broader patterns of morphological and genetic variation across the range of *L. lakedownensis*.

MATERIALS AND METHODS

Allozyme characterization

Genetic analysis was based on tissue samples from 16 specimens of *Leggadina lakedownensis*, aggregated into six populations according to geographic location, and 12 specimens of *L. forresti* (Appendix 1). Liver samples for allozyme electrophoresis were removed from freshly killed animals in the field or at the Western Australian Museum and immediately frozen in liquid nitrogen before being stored at -80°C. Allozyme electrophoresis of liver homogenates was conducted on cellulose acetate gels ('Cellogel') according to the methods of Richardson *et al.* (1986). The following proteins exhibited zymograms of sufficient activity to assign genotypes: aconitase hydratase (ACON, EC 4.2.1.3), aminoacylase (ACYC, EC 3.5.1.14), adenosine deaminase (ADA, EC 3.5.4.4), alcohol dehydrogenase (ADH, EC 1.1.1.1), adenylate kinase (AK, EC 2.7.4.3), albumen (ALB), carbonate dehydratase (CA, EC 4.2.1.1), diaphorase (DIA, EC 1.6.99.), enolase (ENOL, EC 4.2.1.11), fructose-bisphosphatase (FDPASE, EC

3.1.3.11), fumarate hydratase (FUM, EC 4.2.1.2), glyceraldehyde-3-phosphate dehydrogenase (GAPD, EC 1.2.1.12), lactoylglutathione lyase (GLO, EC 4.4.1.5), aspartate aminotransferase (GOT, EC 2.6.1.1), glucose-6-phosphate dehydrogenase (G6PD, EC 1.1.1.49), glycerol-3-phosphate dehyrogenase (GPD, EC 1.1.1.8), glucose-6-phosphate isomerase (GPI, EC 5.3.1.9), glutathione peroxidase (GPX, EC 1.11.1.9), glutathione reductase (GSR, EC 1.6.4.2), isocitrate dehydrogenase (IDH, EC 1.1.1.42), L-lactate dehydrogenase (LDH, EC 1.1.1.27), malate dehydrogenase (MDH, EC 1.1.1.37), "malic" enzyme (ME, EC 1.1.1.40), mannose-6-phosphate isomerase (MPI, EC 5.3.1.8), purine-nucleoside phosphorylase (NP, EC 2.4.2.1), dipeptidase (PEP-A, EC 3.4.13.), tripeptide aminopeptidase (PEP-B, EC 3.4.11.), proline dipeptidase (PEP-D, EC 3.4.13.), phosphoglycerate mutase (PGAM, EC 5.4.2.1), phosphogluconate dehydrogenase (6PGD, EC 1.1.1.44), phosphoglycerate kinase (PGK, EC 2.7.2.3), phosphoglucomutase (PGM, EC 5.4.2.2), pyruvate kinase (PK, EC 2.7.1.40), superoxide dismutase (SOD, EC 1.15.1.1), and triose-phosphate

isomerase (TPI, EC 5.3.1.1). The nomenclature for designating allozymes and multiple loci follows Adams *et al.* (1987).

A phylogenetic analysis using all specimens from both species was undertaken by constructing a neighbor-joining tree (Saitou and Nei, 1987) of Nei (1978) unbiased genetic distance. Because the populations of *L. lakedownensis* could potentially be interbreeding we also investigated their genetic relationships by a principal coordinates analysis (Gower, 1966) using the Cavalli-Sforza and Edwards (1967) arc distance matrix which is Euclidean. These analyses were carried out using Genstat (2000), Biosys-1 (Swofford and Selander, 1989) and Mega version 2.1 (Kumar *et al.*, 2001).

Morphological characterization

Morphological analysis was based on 132 specimens, of which 108 were attributable to *L. lakedownensis* and aggregated into eight geographic populations, and the remainder (24) spread across most of the geographic range of *L. forresti* (Appendix 2). Skulls of *L. lakedownensis* from Queensland were not available for measurement until after the morphological analysis was completed. From the analysis, the significance of the length of the upper molar row was realised and then these measurements of the Queensland specimens were taken, though this group was not used in any multivariate statistical analyses. Skulls from Fowlers Gap and Innamincka (SAM13633, SAM10170) identified as *L. forresti* by Baverstock *et al.* (1976) using karyotypic and biochemical analyses were included herein, as were skulls from Oodnadatta, Birdsville, MacDonald Ranges and Southwest Mann Range (M21623, M21762, M21786, M6344, and M6345), also identified as *L. forresti* by Watts (1976) using morphology.

Figure 2 Skull measurement points.

Twenty measurements of skull, dentary and dental characters and six measurements of external characters (Figure 2) were recorded to the nearest 0.01mm using digital callipers. The measurements were GL, greatest skull length; BD, braincase depth; IPW, interparietal width; BW, braincase width; ZW, zygomatic width; IW, interorbital width; NL, nasal length; NW, nasal width; MW, mastoid width; BUW, width across bullae; BL, basal skull length; M^1L, upper molar 1 length; M^3L, upper molar 3 length; M^1W, upper molar 1 width; M^1M^3L, length of upper molar row; APF, anterior palatal foramen length; PL, palatal length; CIL, dentary condyle to tip of incisor; CAL, tip of coronoid process to posterior edge of angular process; M_1M_3L, lower molar row length. The external measurements were HV, head to vent; TV, vent to tail tip; TAILW, tail diameter measured close to body; PESW, width of pes at hallux; PESL, pes length; EARL, ear length.

M^2L was not measured during this study because its significance in differentiating between *L. lakedownensis* and *L. forresti* was not appreciated at the time of measurement, it was later calculated as $M^1M^3L - M^1L - M^3L$.

Individuals were categorised into three age groups, mature, adult and juvenile according to the extent of tooth-wear and fusion of cranial sutures; mature – extensive tooth wear and sutures fused, adult- some tooth wear and most sutures fused and juveniles- tooth eruption, no tooth wear and sutures unfused. Age was confirmed by examination of the external reproductive status of the animal, fully descended testes or nipple development representing adults and minimal testes descent and button nipples representing juveniles. Three individuals were classified into juvenile and were excluded from all analyses. Appendix 3 lists summary statistics for 20 skull and 6 external variables in *L. lakedownensis* (grouped by geographical region) and *L. forresti*, (all localities pooled).

Initially, we used multiple regressions to investigate and remove any effects of age and sex before further multivariate analyses. These analyses also permitted the detection of statistical outliers and non-normality. For *L. lakedownensis*, each character was regressed on sex, age and locality, and the interactions between these factors. The interactions were examined first because they test for the inter-dependence of the three factors. CAL was the only cranial variable that had a significant interaction (between age and locality). This was a consequence of mean differences between the adults and mature age classes varying between localities. There was also a significant two-way interaction for TAILW (p < 0.01); there was no obvious fat storage in tails. These two variables were not used in any further multivariate analyses. Four variables showed statistically significant sexual dimorphism

at the 5% level of significance (see results) and most variables revealed statistically significant differences between age classes and between localities. We therefore used the estimates of the regression coefficients to remove the age and sex differences while retaining the inter-locality variation. Male and female values were adjusted to the mean of the two sexes, and mature and adult values to the mean of these two age classes. For *L. forresti*, there were not enough individuals of both sexes and each age group to test for interactions or reliably estimate main effects, so sexual dimorphism and age differences in this species were corrected by using the regression estimates made from *L. lakedownensis*. All analysis were repeated with *L. forresti* variables corrected for sex and age effects using regression estimates made from *L. forresti* and results were unchanged.

Canonical variate analysis (discriminant analysis) was used to determine the multivariate relationships between groups. Where a subset of characters was required, they were selected by sequential multivariate analysis of variance, using backward elimination and Wilks' lambda as the selection criteria. All statistical analyses were carried out using Genstat (2000).

RESULTS

Interspecies comparison

Allelic variation was observed at 24 of the 44 putative genetic loci examined (Table 1). The genetic data unequivocally diagnosed *L. lakedownensis* from *L. forresti*, with fixed differences at seven loci (*Acon1*, *Enol*, *Fdp*, *G6pd*, *Got1*, *Gsr*, and *Mdh2*) and major differences in allele frequency at another three loci (*Adh1*, *Gda*, and *Sod*). The unbiased Nei Distance between the species is about 0.28, indicating marked genetic differentiation (Table 2 and Figure 3). In contrast, regional populations of *L. lakedownensis* showed minimal differentiation, with no pairwise Nei Distance greater than 0.033 (Table 2), and only one locus showed any evidence of genetic heterogeneity (ie. a deficiency of heterozygotes) in *L. forresti* (*Ada*, data not shown).

The initial morphological appraisal examined the relationship between *L. lakedownensis* and *L. forresti* by canonical variate analysis of cranial measures to confirm the specific status of these taxa. While there is no overlap in the distribution of the two species on the canonical variate, two *L. lakedownensis* are positioned closer to the *L. forresti* centroid than their own species and so are incorrectly allocated to the wrong species (Figure 4). Because the sample size of *L. forresti* was small, only five traits, selected by backward elimination, were used in this analysis. The canonical variate is a contrast of upper molar 1

Table 1 Sample size for genetic analysis (N), putative allele frequencies at 24 variable loci, and mean heterozygosity (H) in 6 populations of *L. lakedownensis* and in *L. forresti*. length (M¹L) with the other four traits (Table 3). An equivalent analysis using five external measures revealed poor separation of the two species. Furthermore, 20 of 78 *L. lakedownensis* and one of eight *L. forresti* specimens were incorrectly allocated.

Geographic variation within *L. lakedownensis*

Principal coordinates analysis of the six *L. lakedownensis* populations revealed three genetic clusters, namely (a) Queensland, (b) Lissadell and Kakadu, and (c) the Pilbara, Thevenard Island and Mitchell Plateau populations (Figure 5). This outcome can be seen in the genetic distance values, with minimal genetic differentiation between the three Western Australian populations and between the two Northern Territory populations (all Nei Distances < 0.003, Table 2).

Multiple regressions of skull and external measurements revealed that only four variables

Figure 4 Plot of individuals on the canonical variate discriminating *L. lakedownensis* and *L. forresti*.

Trait	Correlation
BD	−0.43
BL	−0.35
M¹L	0.36
M¹M³L	−0.12
CIL	−0.12

Table 4 Correlations between cranial measures and the first and second canonical variates (CV 1 and CV 2) for seven *L. lakedownensis* localities.

Trait	CV 1	CV 2
BUW	0.71	−0.33
BL	0.53	0.24
M¹L	0.30	0.26
M¹W	0.74	0.57
CIL	0.38	0.36

Table 5 Correlations between external measures and the first and second canonical variates (CV 1 and CV 2) for seven *L. lakedownensis* localities.

Trait	CV 1	CV 2
HV	0.21	−0.28
TV	0.79	−0.54
PESW	0.38	0.43
PESL	0.66	0.46
EARL	0.13	0.31

showed statistically significant sexual dimorphism (0.01 < p < 0.05 for all four variables). The male MW average was 0.16mm less than females; male BUW average was 0.15mm less than females; and males had a broader and shorter pes compared to females (PESW 0.19 larger and PESL 0.48 smaller). Most morphometric variables revealed statistically significant differences between age classes and between localities. All variables except APF showed statistically significant differences between localities, most at the 0.001 level. Individuals of *L. lakedownensis* from Thevenard Island and Pilbara mainland localities were larger than individuals from every other locality (Appendix 3).

Canonical variate analysis using cranial measures for the seven localities revealed the Pilbara and Thevenard island populations clustered separately from the other five locations in northern Australia (Figure 6). This analysis was based on five traits selected by backward elimination, but essentially the same results were obtained using all 19 cranial measures or forward selection of the five best (which produced four of the same traits as

backward selection). The first two canonical variates accounted for 73% and 17% of the between group variance (Table 4). The uniformly positive correlations between the five traits and the first canonical function show that this is largely a size discriminator, accounting for the separation of the Pilbara and Thevenard Island populations from the others on this axis. The second canonical variate is a contrast of width across bullae and the other four traits, especially width of M¹.

A parallel analysis using the five external features clearly separated the Thevenard Island population
Figure 6 Plot on the first two canonical variates, using skull variables, of seven *L. lakedownensis* populations showing group centroids and polygons enclosing the range of individuals.
Figure 7 Plot on the first two canonical variates, using external variables, of seven *L. lakedownensis* populations showing group centroids and polygons enclosing the range of individuals.

from the others on the first canonical variate (Figure 7). This axis accounts for 85% of the between-group variation and is positively correlated with all measures (Table 5), this reflects the large size of the Thevenard Island animals, particularly in regard to the length of the tail-vent and pes.

Morphological variation in *L. lakedownensis* and *L. forresti*

Skull and teeth

Differences in skull and tooth morphology of *L. lakedownensis* and *L. forresti* are summarised in Table 6. Figures 8a–c, are dorsal, ventral and lateral photographs of skulls of *L. lakedownensis*, the smaller skull, M16906 and *L. forresti*, the larger skull, M6352. Both species appear quite variable, with especially marked geographic variation in the former species. The molar structure of both species is very similar with variation in the relative size of individual cusps and teeth rather than in their overall shape. From the canonical variate analysis, the variables BD, BL, M^1L, M^1M^3L, CIL were the most significant in diagnosing the two species; these

Figure 8a Dorsal view of *L. lakedownensis*, left, M16906 and *L. forrestii*, right, M6352.

Table 6   Skull character differences between *L. lakedownensis* and *L forresti*.

| *L. lakedownensis*	*L. forresti*
Upper incisor sometimes proodont	Upper incisor not proodont
Rostrum shorter, broader	Rostrum longer, narrower
Braincase "square" dorsally	Braincase "round" dorsally
Braincase shallower	Braincase deeper
Basicranium shorter (except for Thevenard Island animals)	Basicranium longer
Occipital surface of skull relatively flat, with weak nuchal crest	Occipital surface of skull with distinct bulge in supracoccipital region, nuchal crest well-developed
Nasal bone stops short of incisor	Nasal bone usually overlaps incisor
Bullae wider, longer, flatter	Bullae shorter, narrower, more inflated
M^1L generally longer	M^1L generally shorter
M^1 anterior cingulum long	M^1 anterior cingulum short
M^2 shorter relative to M^1	M^2 longer relative to M^1
M_1 longer	M_1 shorter
Dentary angular process large	Dentary angular process finer
Condyle to tip of incisor generally shorter	Condyle to tip of incisor generally longer

are listed as distinguishing characters in Table 6. The two species differ in several cranial and dental charcteristics (Tables 6 and 7). One particularly diagnostic feature is the relative length of M^1 to M^2 (M^1 is relatively longer in *L. lakedownensis*). This reflects the relatively greater development of the M^1 anterior cingular cuspule of L. *lakedownensis*, which approximates cusp t1 in bulk in this species but is much smaller than t1 in *L. forresti*. This difference is reflected in a different overall crown outline for the M^1, with a strongly L-shaped anterolingual inflection in *L. lakedownensis* and a more gently concave inflection in *L. forresti*. Variation in cingular morphology is also observed within *L. lakedownensis*. In Kimberley specimens of *L.lakedownensis* and in *L. forresti* the anterior cingulum extends posteriorly around the lingual face of cusp t1. In contrast, in Pilbara and Thevenard Island specimens, the cingulum terminates on the anterior face of cusp t1.

Across the range of *L. lakedownensis* the incisive foramina only rarely widen posteriorly (Watts, 1976), rather than narrowing as is usual in *L. forresti* and there is only rarely a notch on the upper incisor (Grahame Medlin, pers comm.). No notches on the incisor have been observed in *L. forresti*.

The skull morphology of *L. lakedownensis* is variable across its geographic range, with the upper incisor usually proodontic in Kimberley populations and only occasionally in others; the Pilbara and Thevenard Island animals have larger skull, dental and dentary characters than other populations; and the accessory cusp in the Thevenard Island animals is not as elongated as in other groups.

Externals measurements

Mean values of external characters in *L. forresti* are larger than those of all *L. lakedownensis* populations except Thevenard Island, where the animals approach the size of *L. forresti* (Appendix 3). An exception is mean ear length which distinguishes the two species absolutely. Pes of *L. forresti* are not significantly wider than *L. lakedownensis*, contrary to

Table 7   Table of means and ratios of M^1 and M^2 for adult male and female *L. forresti* and *L. lakedownensis*.

	L. forresti			*L. lakedownesis*

Watts (1976). Mean tail length relative to head and body length for *L. lakedownensis* ranges from 72% in males in the Northern Territory to 91% for males in the Pilbara and 99% for females in Thevenard. For *L. forresti* the mean values are 81% for females and 83% for males.

Pelage and footpads

Unlike *L. forresti*, *L. lakedownensis* is variable in pelage colour, with the palest being Queensland specimens and the darkest being from the Pilbara. *L. forresti* is more rufous dorsally and it has a pure white belly. *L. lakedownensis* is more mouse-like (greyish) in colour overall, with only Queensland and Great Sandy Desert specimens having a white to cream coloured belly, though never as starkly white as in *L. forresti*. The tails of *L. forresti* are generally hairier in appearance than those of *L. lakedownensis*, probably because the hairs are longer in *L. forresti* rather than being more numerous per scale. In general the tail of both species is bicoloured, with the upper part similar in colour to the dorsal fur and the lower part paler, similar in colour to the ventrum fur. Tails of *L. lakedownensis* range from only slightly bicoloured to distinctly bicoloured. In general the pes of both species are cream to white, with the hair on the feet usually the same colour as the ventral hair.

The pattern of pedal variation in the two species is the same although there is some individual variation. For example, the lower pad under the hallux, (the post hallucal pad) is sometimes missing or very indistinct in both species.

Overall, *L. forresti* has a more chestnut dorsal appearance and stark white ventrally. Dorsally, base 50% is dark grey with upper half, buff; ventrally, snow white. Tail with almost no bicolour and some tails hairier than others.

The pelage of *L. lakedownensis* varies across its geographic range. In the Kimberley, at the Mitchell Plateau the dorsum is grey with chestnut tips; the ventrum is grey with chestnut tips; the tail is bicoloured, pale below, brownish above; and the footpads are tiny, sometimes with one indistinct. At Mt Percy, the dorsal fur is chestnut tipped (50% to 33 % of length) over grey; the ventrum is cream; the tail is slightly bicoloured, brown above, cream below; and the footpads are the same as for the Mitchell Plateau population. At Lissadell the dorsal fur is chestnut tipped (33 % of length) over grey; the ventrum is white to creamy with a little grey; the tail is slightly bicoloured to unicoloured; and the footpads are the same as for Mitchell Plateau specimens.

In the Pilbara region, the Thevenard Island specimens have a dorsum that is either chestnut (33%) over brown or all chestnut; the ventrum is either brown with the tip cream or is totally cream; the tail is unicoloured or weakly bicoloured; the

footpads are similar in pattern to other *L. lakedownensis* and variable. At Tom Price the dorsum is chestnut (33%) over grey but with an additional grey tip; the ventrum is grey/cream; the tail is bicoloured, dark grey above, paler below. At Millstream the dorsum is 25% chestnut over dark grey; the ventrum is chestnut/grey or mainly cream with some grey; the tail is bicoloured, grey above, pale below. At Newman the dorsum is 25% chestnut over dark grey; the ventrum is chestnut/grey; the tail is bicoloured as for dorsal and ventral fur. At West Angeles the dorsum 25% chestnut over grey; the ventrum is chestnut/grey; the tail is bicoloured as for the dorsal and ventral fur.

In the Great Sandy Desert the dorsum is almost entirely chestnut; the ventrum almost entirely white; the tail is bicoloured, cream below and pale brown above; the footpads are very small – the post hallucal pad is indistinct.

In Queensland specimens the dorsum ranges between all chestnut to chestnut (50%) over dark grey, through to chestnut (50%) over pale grey; the ventrum ranges from all white to cream; the tail ranges from slightly bicoloured to distinctly bicoloured; and the footpads range from a small indistinct post hallucal pad to distinct post hallucal pad.

In the Northern Territory the dorsum ranges from chestnut (50%) over dark grey with to (50%) chestnut over pale grey; the ventrum ranges from white (66%) over dark grey to white (66%) over pale grey; the tail ranges from slightly bicoloured to distinctly bicoloured; and the footpads range from small indistinct post hallucal pad to distinct post hallucal pad.

DISCUSSION

Prior to 1997, only two specimens of *Leggadina* had been collected from the Pilbara region. However, in the past five years, various faunal surveys by environmental consultants and government scientists have seen some thirty additional specimens collected and lodged in the Western Australian Museum, with other individuals marked and released. It appears, therefore, that *L. lakedownensis* is more widespread and common than previously thought, and perhaps undergoes periods of both population increase and scarcity (Stuart Anstee, pers.com).

A previous study of genetic variation within *Leggadina* (Baverstock *et al.* 1976) examined the karyotype and variation at sixteen allozyme loci, with *L. lakedownensis* represented by only three specimens from Queensland. Using a more geographically diverse range of specimens and many more allozyme loci, this study confirms that the level of genetic differentiation between *L. lakedownensis* and *L. forresti* is substantial and falls

well beyond the range of intra-specific mammalian variation (Nei 1987). Furthermore, the mean heterozygosity within each of the populations accords well with other mammalian species (Nei 1987). The single specimen sampled from the Thevenard Island population was homozygous at all loci; this may reflect genetic drift in an isolate or it may be due to sampling error.

This study indicates that genetic differentiation, as measured by 44 nuclear loci, is minimal between populations of L. lakedownensis across its range. Moro et al. (1998) reported mtDNA differences between populations of L. lakedownensis and noted that the Pilbara and Thevenard Island populations showed the greatest divergence from the other regions. This dichotomy is not supported by the allozyme data, which instead group all three Western Australian populations together to the exclusion of those to the east, and suggest that the Queensland population (albeit represented by a single specimen) is the most differentiated. The Pilbara/Thevenard Island animals are considerably larger than all others; indeed, the Thevenard Island animals in particular are so large that some have suggested that they may represent either a distinct species or a geographic outlier of L. forresti. Neither of these suggestions are supported by any of the three data sets now available. Of course, it might still be argued that the Pilbara/Thevenard Island populations warrant recognition as a distinct subspecies, but the overlap in sizes between the Pilbara and Mount Percy populations, coupled with the lack of any allozyme differentiation in Western Australia, leads us to conclude otherwise.

The skulls of L. lakedownensis and L. forresti can be distinguished using the ratio of M^2L/M^1L and on the degree of elongation of the anterior cingulum on M^1 in L. lakedownensis. Externally, L. forresti can easily be distinguished from L. lakedownensis by its more rufous dorsal and pure white venter. L. forresti also has longer ears than any population of L. lakedownensis.

The skulls of L. lakedownensis morphologically are quite variable including features that might normally be expected to distinguish murine species (e.g. incisor orientation). However, this species has the largest geographic distribution of the two, and therefore experiences a wide variety of habitats and climates. The Thevenard Island population has a much larger body size than the other populations. Pelage pattern also shows marked differences between populations and, together with body size, can be used to confidently assign animals into their appropriate geographic region. L. forresti has a more discrete distribution in central Australia, and this appears to be reflected in the morphologically more homogenous nature of this species.

According to Reid and Morton (1995), the distribution of L. forresti extends further into Queensland and New South Wales than has been surveyed herein. Accordingly, we may not have fully characterized the genetic and morphological diversity present in this species. Based on present knowledge of extant populations, the geographic distributions of the two Leggadina species are clearly disjunct, permitting species identification in the field to be predicted from an animal's geographic location. Fortunately, sufficient differences in their external morphology are available to make this a method of convenience rather than one of need.

In summary, the morphological and allozyme data presented herein demonstrate that the genus Leggadina comprises two allopatric species, L. lakedownensis and L. forresti. These can be diagnosed using both morphological and genetic criteria. Of the two, L. lakedownensis displays more geographic variation than L. forresti, but this variation is nevertheless insufficient to warrant subspecific status for any regional populations.
