Phreodrilidae (Clitellata: Annelida) in north-western Australia with descriptions of two new species

Adrian M. Pinder
Science Division, Department of Environment and Conservation, PO Box 51, Wanneroo, Western Australia 6946, Australia

Abstract - Two new species of oligochaete (Clitellata: Annelida: Phreodrilidae) are described from subterranean waters of the Pilbara and Cape Range regions of Western Australia. Phreodrilus illlici sp. nov. from the Pilbara, most closely resembles Phreodrilus penicillus Pinder 2003, also from the Pilbara, but is less widespread. Insulodrilus angeta sp. nov. occurs primarily in groundwater, especially within the Ashburton catchment of the Pilbara, but was also collected from two Pilbara springs and from a cave on Cape Range. These, and other undescribed phreodrilids, suggest that north-western Australia, despite being an arid zone, is surprisingly rich in this Gondwanan family.

INTRODUCTION

Thirty two species of Phreodrilidae (in 6 genera) have been described from Australia to date (Pinder 2003b) but at least as many species again await description. The family Phreodrilidae is common in streams and lentic wetlands of temperate southern Australia and particularly diverse in Tasmania and south-western Australia (Pinder and Brinkhurst 1997). The concentration of species in the most temperate parts of Australia fits with the idea that the family is Gondwanan in origin (Martin et al. 2008, Pinder and Brinkhurst 1997). However, while the family is far less widespread in more xeric parts of Australia, new species are increasingly being collected from groundwater and groundwater associated wetlands outside of the temperate zones. Pinder (2003a) described the first endemic aquatic oligochaete, Phreodrilus penicillus, from the arid north-west of Western Australia. Examination of additional material has revealed the presence of numerous other oligochaetes in the region, including some new stygobiotic species. These are part of a regional stygofauna that, with > 350 species in the Pilbara, is particularly diverse by world standards (Eberhard et al. 2005; Eberhard et al. in press; Humphreys 1999; Humphreys et al. 2005). In this paper, two new phreodrilids are described and the distribution of the family in the north-west is discussed. Undescribed phreodrilids mentioned in the discussion are coded as Phreodrilus WA12, Phreodrilus WA32, Insulodrilus WA35 and phreodrilid WA36 and will be described at a later stage.

This material was collected during several projects: a survey of epigean and hypogean aquatic invertebrates of the Pilbara (Pilbara Biological Survey [PBS], Department of Environment and Conservation: Eberhard et al. (in press) and unpublished data), the Monitoring of River Health Initiative (MRHI) and surveys by Dr W.F. Humphreys of the Western Australian Museum.

METHODS

Groundwater specimens were collected using haul nets as described in Eberhard et al. (in press) and preserved in 100% ethanol. For the PBS bore sites, oxygen, redox and pH were measured in-situ using a Yeo-Cal meter and ionic composition and total dissolved solids were analysed from samples collected using a bailer. Surface water specimens were collected with a 250μm mesh sweep net and preserved in 100% ethanol. Specimens from New Mowbowra Cave were collected by hand from floating root mats. Specimens were stained in Grenacher's borax carmine, dehydrated in isopropanol, cleared in Histoclear and slide mounted in Permount. Drawings were made with the assistance of a drawing tube and measurements were made using Auto-Montage Pro 5.01 (The Synoptics Group 2003) with a JVC KY-F1030 video camera calibrated with a stage micrometer.

Type material is deposited with the Western Australian Museum (WAM) and additional material is held by the Department of Environment and Conservation (DEC). Geographic coordinates were measured with a hand-held GPS using datum GDA94, except for New Mowbowra Cave which was either AGD66 or AGD84.

The following abbreviations are used
Figure 1  Map showing collection localities for *Insulodrilus* spp. and an unidentified phreodrilid (top) and *Phreodrilus* spp. (bottom). Solid lines represent drainage basins as named. Immatures tentatively allocated to *Insulodrilus* or *Phreodrilus* on the basis of the form of the ventral chaetae.
throughout the text: a, atrium; bd, broad portion of spermathecal duct; cm, circular muscle on spermathecal duct; ed, ectal portion of spermathecal duct; ff, female funnel; md, median portion of spermathecal duct; mf, male funnel; p, pendant penis; pp, pseudopenis; sa, spermathecal ampulla; sd, spermathecal duct; sv, spermathecal vestibule; v, vas deferens. Roman numerals denote segment numbers while numbers in Arabic separated by a slash refer to septa between segments.

SYSTEMATICS

Family Phreodrilidae Beddard 1891

Phreodrilus Beddard 1891

Type species

Phreodrilus subterraneus Beddard 1891, by original designation.

Remarks

Phreodrilus was established for P. subterraneus by Beddard (1891) from groundwater in New Zealand but is now also known from another groundwater species in New Zealand, five from Australia (all but one epigean) and one groundwater species from the Arabian Peninsula (Martinez-Ansemil et al. 2002). The genus is one of the few currently recognised phreodrilid genera with a distinct apomorphy, the coiled protrusible pseudopenis within a muscular sac, which can be everted to form a copulatory organ greater than the body width. Phreodrilus pelliculS was described from springs in the Pilbara (Pinder 2003a) and has subsequently been collected from groundwater in the same region (Figure 1).

Phreodrilus linnaei sp. nov.

Material examined

Holotype

Australia: Western Australia: Main Roads Department groundwater bore HMBR#1 on Hamersley Mount Bruce Road about half way between Karajini Drive and Nanutarra-Munjina Road (site PSS043 of PBS), Fortescue River catchment, 22°30'06.3"S 117°57'38.3"E, 21 November 2002, collected using a haul net, M. Scanlon, J. Cocking (WAM V7430; slide mounted).

Paratypes

Australia: Western Australia: 2 specimens, collection details as for holotype (WAM V7431, V7432; slide mounted).

Diagnosis

The combination of a protrusible pseudopenis and a small pendant penis in P. linnaei is otherwise found only in P. pelliculS, also from the Pilbara region. However, P. pelliculS lacks an enlarged mid-portion of the spermathecal duct, has a broad uncoiled pseudopenis and has a larger body (up to 520 μm at X), larger anterior ventral chaetae (80–120 μm) and shorter maximum hair length (up to 325 μm). The complex spermathecal ducts of P. linnaei, with the widened medial portion, are unique within the family.

Description

Length unknown, all specimens with posterior missing; width at III 200–210 μm and at XI 310–350 μm. Prostomium bluntly conical to rounded. Pharynx heavily glandular and muscular in I and II, oesophagus thin walled in III-VIII, enlarging into intestine in VIII. Pharyngeal glands not heavily developed, located ventral and sometimes lateral in IV to V or VI.

Ventral chaetae paired from II, one of each pair bifid, slightly sigmoid, with rudimentary upper tooth and distinct distal nodulus, the other sharply single-pointed, straighter and without nodulus, both 72–85 μm in anterior segments (Figure 2D). Ventral chaetae absent on XII, present but unmodified on XIII. Dorsal chaetae dorso-lateral from III, each bundle with 1–2 smooth hairs, each surrounded by a pair of support chaetae that do not emerge from the body wall. Hairs 180–524 μm long and 1.5 to 2.5 μm wide at body wall, tapering to a fine tip, generally increasing in size posteriorly over first few segments.

Clitellum from 1/2XII to end of XIII, clitellar epithelium 2–3 times width of somatic body wall and consisting of irregular ovoid to rectangular cells. All genitalia and pores paired. Male pores ventro-lateral halfway between 11/12 and 12/13 in line with the ventral chaetae. Female pores and ducts not visible on types. Dorso-lateral slit-shaped openings of the spermathecal vestibulae in intersegmental furrow 12/13, in line with dorsal chaetae.

Testes and ovaries antero-ventro-lateral in XI and XII respectively. Developing sperm present from VI to XII. Ventral-lateral cup-shaped sperm-tunnels on 11/12, each narrowing to a vas deferens of 8–13 μm width which enters pseudopenial sac entally where sac meets atrium. Atrium (Figure 2A-a) consisting of a short blunt (85–108 μm x 24–50 μm) ‘tail’ on the pseudopenial sac with uneven lining tissue, transforming into a pseudopenis (i.e. with lining tissue dissociated from muscular sac wall) just before joining the vas deferens. Eversible pseudopenis (Figure
Figure 2  
*Phreodrilus linnarii* sp. nov.: A, male genitalia, based mostly on holotype other than ental atrium which is an interpretation from partly obscured and folded atria of the 3 type specimens; B, spermathecal duct of holotype; C, genitalia of holotype *in situ*, D, ventral chaetae of holotype. Scale lines: 50µm.
Phreodrilidae in north-western Australia

2A--pp) 15–30 μm wide, loosely coiled within sac and with ciliated lumen about 1/3 width of duct. Sac up to 115 μm wide, narrower at either end, ectally forming a duct (20–40 μm wide) containing the (now unciiliated) pseudopenis, the whole duct protruding into the penial sac to form a short (15–45 μm long x 25–26 μm wide) double-walled pendant penis occupying 1/3 to 1/2 of the penis sac.

Spermathecal ampullae (Figure 2B--sa) elongate, with walls mostly consisting of lining tissue (4–6 μm), muscle not visible, and loosely folded in XIV and XV, filled with sperm in loose masses in mated individuals. Ampulla narrowing ectally to form a short duct (Figure 2B--md) of varying width (19–33 μm) and length (130–160 μm), with a narrow lumen, broader lining tissue and a circular muscle layer. The latter opens into a broader glandular section of duct (180–270 x 40–85 μm) with large lining cells and a very thin muscle layer (Figure 2B--bd), which then narrows to form a loose duct (width 25–35 μm) (Figure 2B--ed). This duct covered by longitudinal muscles in its ectal portion which branch off as long thin fibres (Figure 2B--mf) that join the body wall at various points.

Remarks

The term protrusible pseudopenis was used by Brinkhurst (1965) to describe the portion of the male genital ducts that is a slightly to strongly coiled and ciliated tube within a thin-walled sac of Phreodrilus species. This tube is everted from the male pore during copulation. This has been thought of as a modification of the ectal part of the atrium, which is normally a glandular organ consisting of an inner layer of glandular lining cells around a lumen and an outer layer of muscle cells. Such a modification from atrium to protrusible penis could have arisen by separation of the lining tissue from the muscle tissue, leaving a tube (protrusible penis) within a tube (sac) (Brinkhurst 1965). However, the lumen of the standard atrium is never ciliated whereas vasa deferentia (which normally feed into the atria) are ciliated. This suggests that the mostly ciliated protrusible penes of Phreodrilus may in fact be highly modified vasa deferentia (P. Martin, Institut Royal des Sciences Naturelles de Belgique, pers. comm.) rather than atria. Cilia are absent from the most ectal part of the pseudopenis, but modified vasa deferentia of some of the species lack cilia ectally (Custavsson and Erseus 1999). In most other aquatic oligochaetes the penes are conical to elongate structures located within an invagination of the body wall at the external opening of the male duct and often referred to as pendant penes. While the coiled structures present in Phreodrilus are clearly not homologous to pendant penes, they nonetheless perform a penis-like function of sperm transfer and the term protrusible pseudopenis remains apt.

The small pendant penis present in all specimens of P. peniculus and P. linnaei does not appear to be the same as the partially everted pseudopenis that is occasionally seen in other Phreodrilus specimens, e.g. as illustrated for Phreodrilus stocki (Martinez-Ansemil et al. 2002).

Water sampled from the type locality was neutral freshwater dominated by sodium and bicarbonate (Table 1).

Etymology

Named in honour of Carolus Linnaeus (1707–1778) on the 250th anniversary of the publication of the 10th edition of Systema Naturae and the 300th anniversary of his birth.

Insulodrilus Brinkhurst 1991

Type species

Phreodrilus lacustris Benham 1903, by original designation.

Remarks

Insulodrilus was established following a phylogenetic analysis by Brinkhurst (1991) for species with pendant penes and with female pores not located within the (generally small) spermathecal vestibulae. However, Brinkhurst noted that this grouping was probably paraphyletic and only an interim 'conservative measure'. Species of the otherwise similar Astacopsidrillls (Goddard, 1909) are distinguished from Insulodrilus by the presence of female pores that are located within greatly enlarged spermathecal vestibulae. However, these are characters of degree and some Insulodrilus have well developed spermathecal ampulla and some Astacopsidrillls have female pores spermathecal pores only just within or co-incident with the openings of the vestibulae. Future analyses of the family Phreodrilidae will most likely result in these genera being synonymised or (perhaps more likely) split into multiple smaller genera. The new species below has moderately well developed vestibulae with separate female pores. The genus occurs in New Zealand, South America, Africa and Australia. Eight species have previously been described from Australia, with most known only from Tasmania.

Insulodrilus angela Benham 1903, by original designation.

Insulodrilus angela sp. nov.

Figure 3
Material examined

Holotype

**Australia: Western Australia:** bore WAWB51, West Angelas mine site, approximately 100 km NW of Newman (PBS site PSSI67), 23°09'11.6"S, 118°44'51.3"E, 14 October 2004, H. Barron, J. Cocking (WAM V7433, slide mounted (left coverslip).)

Paratypes

**Australia: Western Australia:** 1 specimen on same slide (right coverslip) as holotype, collection details as for holotype (WAM V7434); 2 specimens, Nyeebury Spring (site PSW016 of PBS), 21°51'29"S, 116°30'57"E, 15 May 2005, A. Pinder, J. McRae (WAM V7435, slide mounted); 1 specimen, Nyeebury Spring (site ONS03 of MRHI), 21°51'36"S, 116°30'42"E, 11 May 1996, W. Kay, M. Smith (WAM V7436; slide mounted); 1 specimen, Bore WB32, West Angelas Mine, Pilbara, 23°09'48"S, 118°41'05"E, 118°44'51.3"E, 12 October 2004, J. Cocking, H. Barron (WAM V7438; slide mounted (right coverslip) as holotype, 118°13'02.1"E, 22°43'32.6"S, 118°48'02.4"E, 20 August 2004, M. Scanlon, H. Barron (WAM V7439; slide mounted); 1 specimen, Bore YR15/73, Pilbara, 22°43'32.6"S, 118°48'02.4"E, 11 May 1996, W. Kay, M. Smith (WAM V7440; slide mounted).

Other material examined

**Australia: Western Australia:** 2 specimens, Millstream Delta (PBS site PSW011, a warm spring), Millstream National Park, Pilbara, 21°34'58"S, 117°04'08"E, 24 August 2003, A. Pinder, J. McRae (DEC slide 188); 1 specimen, Bore TCS002 (site PSS394 of PBS), Pilbara, 22°43'32.6"S, 118°48'02.4"E, 20 August 2004, M. Scanlon, H. Barron (DEC slide 202).

Diagnosis

*Insulodrilus angela* differs from other described *Insulodrilus* primarily in the size and form of the spermathecal vestibule and the un-modified somatic chaetae. Other species lacking modified somatic chaetae are *I. lacustris* s. *l. (see Remarks), I. martensi* Martin and Giani 1995 (from Africa, with alveolate penes, thickened septa in the genital region and short stiff hairs), *I. genitalisitifera* Martin and Brinkhurst 1994 (also from Africa, with genital chaetae in XI and XIII and an alveolate penis) and *Insulodrilus lacustris* Michaelsen 1903 (from the subantarctic Campbell Island, with long slender atria, smaller spermathecal vestibules and ventral chaetae as described for *lacustris*).

Description

Body of slide-mounted specimens 170–290 μm wide at III, 225–375 μm wide at X, most specimens missing posterior but one complete specimen 6.05mm. Prostomium rounded and conical, pharynx in III, strongly muscular posteriorly with thick muscle connections to dorso-lateral body wall of II-V. Pharyngeal glands on lower half of anterior and posterior sides of septa 4/5 to 6/7 or 7/8 and laterally on oesophagus in V to VII. Oesophagus widening into gut in VIII-X.

Ventral chaetae (55–80 μm) from II, all paired and bifid with small but distinct upper teeth (Figure 3A). Ventral chaetae of XIII modified: one long (85–105 μm) and hollow tipped, protruding either end of the large spermathecal chaetal gland, the other short and not protruding. Ventral chaetae of XII absent. Dorsal chaetae from III, 1 to 2 smooth hairs, each surrounded by a pair of support chaetae, mostly 110–480 μm long (rarely shorter), tapering evenly to a fine tip.

Genitalia paired. Male pores ventro-lateral in posterior third of XII in line with the ventral chaetae. Testes antero-ventral in XI, ovaries antero-ventral in XII. Female ducts penetrate 12/13 to exit at pores immediately anterior of the opening of the spermathecal vestibule antero-ventral on XIII in line with the ventral chaetae (Figure 3B–ff). Thin clitellum from 1/2 XII to end of XIII, not developed ventrally on XII.

Narrow (7.5 to 9.5μm) ciliated vas deferens (Figure 3B–v) joins elongate (35–44 μm wide, 270–540 μm long) unciliated atrium (Figure 3B–a) as the latter narrows just before entering penis (join not visible on holotype but seen on some paratypes). Atrium with lumen of variable width, probably reflecting reproductive stage. Slender pendant penis occupying most of the penis sac. Spermathecal vestibule vase-shaped ectally (Figure 3B–sv) with longitudinal muscle layer and numerous muscle filaments extending from the vestibule to the dorso-lateral body wall and septa. The vestibule dilated at its dorsal extremity and surrounded by circular muscle tissue (Figure 3B–cm), bending posteriorly to join a spermathecal duct (Figure 3B–sd) above the spermathecal chaetal gland. Ducts joining voluminous ampullae in XIV, which extends into at least XV. Sperm in loose oval bundles in ampulla.

Remarks

These specimens were at first identified as *Insulodrilus lacustris* s. *l.*, the suffix indicating that...
this name has been given to what now appears to be a complex of similar species in Australia.

Despite indications to the contrary by Pinder and Brinkhurst (1997), the Australian specimens differ from *I. lacustris* s. str. (as described by Benham, 1903 from New Zealand specimens) in a number of respects. In contrast to all Australian forms, *I. lacustris* has narrow and simple spermathecal vestibulae, hardly differentiated from the duct apart from the presence of longitudinal muscles in the former and circular muscles in the latter. They also have dorsal chaetae that project only 1/3 to 1/3 the body height and scarcely half the segment length (whereas most Australian forms have the hair chaetae as long as or longer than the body height) and have anterior ventral chaetae with one chaeta of a pair clearly bifid and the other almost simple (just a rudimentary hint of a tooth) whereas in Australian specimens both chaetae in all ventral pairs are always distinctly bifid.

The several forms of *lacustris*-like *Insulodrilus* in Australia differ in the extent of development of the spermathecal vestibule and ducts, length of the atrium, body size, chaetal size and a number of other features. The states of these characters seem consistent and distinct within geographic regions and sufficient to recognise a number of species, including *I. angela* and another undescribed Pilbara species *Insulodrilus* WA35. Almost all phreodrilids have limited geographic distributions (Pinder and Brinkhurst, 1997; Pinder 2001) and the recognition that the Australian “lacustris” are in fact multiple endemic species fits this pattern.

All specimens were collected in circum-neutral fresh to slightly brackish (≤2.4g/L) water with variable ionic composition, including dominance by sodium with bicarbonate, or magnesium with chloride, sulphate or bicarbonate.

**Etymology**

This species is named after the type locality, a bore near West Angela Hill.

**DISCUSSION**

The global distribution of the Phreodrilidae indicates a Gondwanan origin (Martin et al. 2008. Pinder and Brinkhurst 1997) and, to date, the majority of species have been found in places that seem to offer refugia from past or present aridity: alpine areas, high southern latitudes, groundwater or deep lakes. *Astacopsodrilus echondi* Pinder 2003, which occurs in ephemeral seepages on granite outcrops, is an apparent exception, though nothing is known of where it survives when the seepages are dry. The occurrence of seven (mostly still undescribed) phreodrilids in the arid Pilbara is further evidence that the family occurs more widely within Australia than previously thought. Their occurrence mostly...

indicates that the full picture of phreodrilid distributions in the Pilbara is yet to be revealed.

Springs fed by discharging groundwater or hyporheic flow are present throughout the Pilbara region and the occurrence of the same phreodrilid species in both these springs and in groundwater suggests that the springs are a portal for movement between surface and groundwater. Epigean movement within catchments, and between catchments when coastal floodwaters merge, would also be enhanced by the regular and severe floods resulting from cyclonic rains. Changes to flow paths and isolation of ancient river tributaries by rising sea levels have perhaps also contributed to the occurrence of these species across present catchment divides. For example, the Fortescue River formerly flowed to the coast via what is now the lower Robe River but is now entirely separate. Similarly, the Ashburton River, which now flows to the coast near Onslow, is believed to have been in close proximity to Cape Range between the Middle Miocene and Late Pleistocene (Wyrwoll et al. 1993), bringing it much closer to the record of L. angela from the Cape. Knott (1993) advanced the latter concept as an explanation for the presence of the limnostygobiont shrimp Stygiocharis stygicola and two subterranean fish species on the Cape, all three of which co-occurred with L. angela in New Mowbowra Cave (W.F. Humphreys, Western Australian Museum, pers. comm.).

ACKNOWLEDGEMENTS

The Pilbara Biological Survey was funded by the Department of Environment and Conservation Western Australia, the Australian Government through the Natural Heritage Trust, and Straits Resources. The Monitoring of River Health Initiative was funded by the Commonwealth Government through the National Heritage Trust and Land & Water Australia and by the State Government through Department of Environment and Conservation and the Water and Rivers Commission. William Humphreys of the Western Australian Museum kindly provided specimens and data collected with financial assistance from the National Estates Program, the Heritage Council of Western Australia, the Water Authority of Western Australia and the Western Australian Museum. Susan Jones helped prepare the map. Mike Scanlon assisted with slide mounting and identifying some of the specimens.
